### INTRODUCTION

What might affect the evolution of mutation rates?  
Biophysical limitation of functional protein complex.  
Mutational load due to the deleterious effects of mutations.  
Linkage effects of beneficial mutations.  
Genetic-drift barrier.

How fast can the evolution of mutation rates happen in different populational-genetic environments?

Can we observe different evolutionary outcomes of mutation rates in different kinds of environment?

### MATERIALS AND METHODS

We evolved *Escherichia coli* with two genetic backgrounds for 900 days.

Genetic background	Point mutation rate per clone per generation
MMR-	0.151
WT	0.001

(Lee et al. 2012)

### Experiment I: three transfer sizes (TSs) for bottleneck effects

### Experiment II\*\*: three transfer periods (TPs) for starving effects

### CONCLUSIONS

In experiment I, most MMR- lines experienced a reduction of mutation rate by 10-100 fold, while WT lines do not. In contrast, in experiment II, we surprisingly found both WT and MMR- lines from the intermediate TP (10) evolved higher mutation rates. These results suggest that the mutational load remains an important factor to constrain the evolution of high mutation rate. However, that constraint can be overcome by extra evolutionary opportunities provided under some special conditions, such as a fluctuating environment of resource availability.

Our collection of pooled-sequencing data also allows us to study genetic basis of the evolution of mutation rates. For example, several structural variations in *mutL* were found in 10-day, WT lines.
